

## Pharmacogenomics

Yossi Levy

## Central Dogma of Molecular Biology

$\square$

- Genome - contains all biological information
- Biological information is encoded in DNA
- DNA is divided to discrete units called Genes
- Genes are packed into Chromosomes
- DNA is made of four bases: A, G, C and T

## Alleles and expression

- Each gene is represented by two copies, called Alleles
- Genotype - Combination of alleles
- Homozygous gene - both alleles are the same
- Heterozygous gene - alleles are different
- Phenotype- expression of genotype
- A dominant allele is almost always expressed
- A recessive allele is expressed only if there are two copies of that allele
- Some expressed traits are attributed to variation in DNA sequence
- When two individuals display different phenotypes in the same trait, they have two different alleles in the same gene.
- That gene is therefore said to be polymorphic.

## The Human Genome

- 46 chromosomes - 23 pairs
- 2 meters of DNA
- 3 billion DNA bases
- 25000 genes
- 10 million SNPs

- SNP - Single Nucleotide Polymorphism
- Most common type of genetic variation
- Each SNP represent a difference in a single DNA base
- The SNP in the picture is CT or AC or AG or GT they are all the same
- SNP can have 3 possible values: AA, Aa or aa

## Types of genetics studies

Studies to investigate genotype-trait association within a population of unrelated individuals:

- Candidate polymorphism studies
- Candidate gene studies
- Fine mapping studies
- Gnome-wide association studies (GWAS)

## Candidate polymorphism studies

謀部

- Consider polymorphism(s) within a gene
- There is an a priori hypothesis about functionality
- Primary hypothesis: the variable site under investigation is functional.
- That is, the given SNP (or set of SNPS) influence the disease trait directly

Candidate gene studies

- Consider multiple SNPs within a gene
- SNPs are not assumed to be functional
- However, the selected SNPs may be associated to a functional SNP within the gene
- This association is called Linkage Disequilibrium
- Set to identify with a high level of accuracy the location of a disease-causing variant

## Gnome Wide Association Studies

- Similar to candidate gene approach
- Aim to identify association between SNPs and trait
- Less hypothesis driven
- Involves the characterization of a much larger number of SNPs

## Hardy-Weinberg Equillbrium

- A theoretical description of the relationship between genotype and allele frequencies
- HWE denotes independence of the alleles at a single site between two homologous chromosomes
- Let $p$ be the frequency of the dominant allele $A$ and $q$ and let be the frequency of the recessive allele $a(p+q=1)$.
- The expected genotype frequencies are:

$$
\begin{aligned}
& p_{A A}=p^{2} \\
& p_{A a}=2 p q=2 p(1-p) \\
& p_{a a}=q^{2}=(1-p)^{2}
\end{aligned}
$$

## Testing HWE

|  | Homolog 2 |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | A |  |
| Homolog 1 | A | $\mathrm{n}_{11}$ | $\mathrm{n}_{12}$ | $\mathrm{n}_{1 .}$ |
|  | a | $\mathrm{n}_{21}$ | $\mathrm{n}_{12}$ | $\mathrm{n}_{2 .}$ |
|  |  | $\mathrm{n}_{\cdot 1}$ | $\mathrm{n}_{2}$ | n |

- $\mathrm{n}_{12}$ and $\mathrm{n}_{21}$ are not observed. Only $\mathrm{n}^{*}{ }_{12}=\mathrm{n}_{12}+\mathrm{n}_{21}$ is known
- $p_{A}$ is estimated by $\left(2 n_{11}+n_{12}\right)^{2} / 2 n$
- Using the estimate for $p_{A}$ we can calculate the expected counts $\mathrm{E}_{11}, \mathrm{E}^{\star}{ }_{12}$ and $\mathrm{E}_{22}$ corresponding to $\mathrm{n}_{11}, \mathrm{n}^{*}{ }_{12}$ and $\mathrm{n}_{22}$ and construct a goodness of fit Chi-square test
- Another option is using Fisher's Exact test

| Genotype | AA | AC | CC |
| :---: | :---: | :---: | :---: |
| Count $\left(n_{i}\right)$ | 48 | 291 | 724 |
| Expected $\left(O_{i}\right)$ | 35.22 | 316.55 | 711.22 |

$p_{A}=\frac{2 \cdot 48+291}{2 \cdot 1063}=0.182 \longleftrightarrow$ MAF - Minor Allele Frequency
$O_{A A}=1063 \cdot 0.182^{2}=35.22$
$O_{A C}=1063 \cdot 2 \cdot 0.182 \cdot(1-0.182)=316.55$
$O_{C C}=1063 \cdot(1-0.182)^{2}=711.22$
$\chi^{2}=\frac{(48-35.22)^{2}}{35.22}+\ldots=6.927>3.84=\chi_{1,0.05}^{2}$

HWE implications

- HWE implies constant alleles frequencies over generations
- HWE is violated in the presence of population admixture - a situation in which mating occurs between two populations for which the allele frequencies differ
- HWE is violated in the presence of population stratification - combination of populations in which breeding occurs within but not between subpopulations
- HWE is violated when mating occurs between relatives

## Deviation from HWE

- Check if population admixture or stratification is present
- Approaches: covariates, PCA, MDS
- May indicate genotyping error

## Linkage Disequilibrium

- Recall that in candidate gene studies and GWAS, studied SNPs may not be functional
- However, it is hoped that they are associated with the trait under consideration
- LD: an association in the alleles present at each of two sites present on a genome

Expected allele distributions under independence

|  |  | $B$ | Site 2 |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  | $B$ |  |  |
|  |  | $n_{11}=N p_{A} p_{B}$ | $n_{12}=N p_{A} p_{b}$ | $n_{1 .}=N p_{A}$ |
| Site 1 |  |  |  |  |
|  | $a$ | $n_{21}=N p_{a} p_{B}$ | $n_{22}=N p_{a} p_{b}$ | $n_{2 .}=N p_{a}$ |
|  |  | $n_{.1}=N p_{B}$ | $n_{.2}=N p_{b}$ | $N=2 n$ |

Observed allele distributions under LD

|  |  | $B$ | Site 2 |
| :---: | :---: | :---: | :---: |
|  |  | $b$ |  |
|  | $A$ | $n_{11}=N\left(p_{A} p_{B}+D\right)$ | $n_{12}=N\left(p_{A} p_{b}-D\right)$ |
| Site 1 |  | $n_{21}=N\left(p_{a} p_{B}-D\right)$ | $n_{22}=N\left(p_{a} p_{b}+D\right)$ |
|  | $a$ | $n_{12}$ | $n_{2 .}$ |
|  |  | $n .2$ | $N=2 n$ |

## Estimation of D

$$
\hat{p}_{A}=n_{1 .} / N \quad \hat{p}_{B}=n_{.1} / N \quad \hat{p}_{A B}=? ? ?
$$

The number of individuals with $A$ and $B$ on the same allele is not observed

## Estimation of $p_{A B}$

Genotype counts for two biallelic loci

$$
\begin{aligned}
& \log L\left(\theta \mid n_{11}, \ldots, n_{33}\right) \propto\left(2 n_{11}+n_{12}+n_{21}\right) \log p_{A B} \\
&+\left(2 n_{13}+n_{12}+n_{23}\right) \log p_{A b}+\left(2 n_{31}+n_{21}+n_{32}\right) \log p_{a B} \\
&+\left(2 n_{33}+n_{32}+n_{23}\right) \log p_{a b}+n_{22} \log \left(p_{A B} p_{a b}+p_{A b} p_{a B}\right)
\end{aligned}
$$

$p_{A b}=p_{A}-p_{A B}, p_{a B}=p_{B}-p_{A B}$ and $p_{a b}=1-p_{A}-p_{B}-p_{A B}$.

$$
D^{\prime}=\frac{|D|}{D_{\max }}
$$

$$
D_{\max }= \begin{cases}\min \left(p_{A} p_{b}, p_{a} p_{B}\right) & D>0 \\ \min \left(p_{A} p_{B}, p_{a} p_{b}\right) & D<0\end{cases}
$$

## Another approach for LD

|  |  | $B$ | Site 2 | $b$ |
| :---: | :---: | :---: | :---: | :---: |
|  |  | $A$ | $n_{11}=N\left(p_{A} p_{B}+D\right)$ | $n_{12}=N\left(p_{A} p_{b}-D\right)$ |
| Site 1 |  | $n_{1 .}$ |  |  |
|  | $a$ | $n_{21}=N\left(p_{a} p_{B}-D\right)$ | $n_{22}=N\left(p_{a} p_{b}+D\right)$ | $n_{2 .}$ |
|  |  | $n_{.1}$ | $n .2$ | $N=2 n$ |

- Calculate "Pearson's chi-square statistic" for this table
- Define

$$
r^{2}=\chi^{2} / N
$$

- However, be aware that the " p -value" associated with the chi-square statistic is not valid

Relationship between $r^{2}$ and $D$

$$
\begin{aligned}
& \chi^{2}=\sum_{i, j} \frac{\left(o_{i j}-E_{i j}\right)^{2}}{E_{i i}}=\sum_{i, j} \frac{(N \cdot D)^{2}}{E_{i i}}= \\
& =(N D)^{2} \cdot\left(\frac{1}{N p_{A} p_{B}}+\frac{1}{N p_{A} p_{b}}+\frac{1}{N p_{a} p_{B}}+\frac{1}{N p_{a} p_{b}}\right)= \\
& =\frac{N D^{2}}{p_{A} p_{B} p_{a} p_{b}} \\
& \quad r^{2}=\frac{\chi^{2}}{N}=\frac{D^{2}}{p_{A} p_{B} p_{a} p_{b}}
\end{aligned}
$$

## LD graphical presentation

Trait-genotype relationship

- Ultimate goal: identify SNP or set of SNPs that predict the phenotypic trait
- In pharmaceutical industry - the interesting trait is response to treatment

## Logistic regression

- Goal: relate explanatory variables x to a binary response variable y
- Let $\mathrm{y}^{*}$ be a continuous variable. It is not part of the data, only part of the model
- Model relationship between $y^{*}$ and $x$ using simple linear regression: $y^{*}=\beta_{0}+\beta_{1} x+\varepsilon$
- Model the relationship between y and $y^{*}$ as a function of the sign of $y^{*}: y=1$ if $y^{*}>0,=0$ otherwise
- Assume that the errors $\varepsilon$ follow a logistic distribution:

$$
F(t)=\frac{\exp (t)}{1+\exp (t)}
$$

## Logistic regression

$$
\begin{aligned}
& P(y=1 \mid x)=P\left(y^{*}>0 \mid x\right)= \\
& =P\left(\beta_{0}+\beta_{1} x+\varepsilon>0 \mid x\right)= \\
& =P\left(\varepsilon>-\left(\beta_{0}+\beta_{1} x\right)\right) \\
& =P\left(\varepsilon<\beta_{0}+\beta_{1} x\right)= \\
& =\frac{\exp \left(\beta_{0}+\beta_{1} x\right)}{1+\exp \left(\beta_{0}+\beta_{1} x\right)} \\
& \Rightarrow \\
& \log \frac{P(y=1 \mid x)}{P(y=0 \mid x)}=\beta_{0}+\beta_{1} x
\end{aligned}
$$

$$
L(\theta)=\prod\left[P\left(y_{i}=1 \mid x_{i}\right)\right]^{y_{i}}\left[1-P\left(y_{i}=1 \mid x_{i}\right)\right]^{1-y_{i}}
$$

Denote $\pi_{\mathrm{i}}=P\left(y_{i}=1 \mid x_{i}\right)=\frac{\exp \left(\beta_{0}+\beta_{1} x\right)}{1+\exp \left(\beta_{0}+\beta_{1} x\right)}$

$$
l(\theta)=\sum\left(y_{i} \log \pi_{\mathrm{i}}+\left(1-y_{i}\right) \log \left(1-\pi_{\mathrm{i}}\right)\right)
$$

## Comparing logistic models

- Let $M$ and $M$ ' be two logistic regression models

$$
\begin{aligned}
& \mathrm{M}: \log \frac{P\left(y=1 \mid x_{1}, \ldots, x_{p}\right)}{P\left(y=0 \mid x_{1}, \ldots, x_{p}\right)}=\beta_{0}+\beta_{1} x_{1}+\ldots+\beta_{p} x_{p} \\
& \text { M }: \log \frac{P\left(y=1 \mid x_{1}, \ldots, x_{p}, x_{p+1}, \ldots, x_{p^{\prime}}\right)}{P\left(y=0 \mid x_{1}, \ldots, x_{p}, x_{p+1}, \ldots, x_{p}\right)}=\beta_{0}+\beta_{1} x_{1}+\ldots+\beta_{p} x_{p}+\beta_{p+1} x_{p+1}+\ldots+\beta_{p} x_{p^{\prime}}
\end{aligned}
$$

- Let $|\mathrm{M}|$ and $|\mathrm{M}|$ be the dimensions of the models
- Let I* $(\mathrm{M})$ be the maximum value of the log-likelihood function of model M
- Let the deviance of model $M$ be $D(M)=-\left.2\right|^{*}(M)$
- Since $I^{*}(M) \leq l^{*}\left(M^{\prime}\right)$ then $D(M) \geq D\left(M^{\prime}\right)$
- Note that this result holds because the models are nested

## Comparing logistic models

To test the hypothesis

$$
H_{0}: \beta_{p+1}=\ldots=\beta_{p^{\prime}}=0
$$

one can use the likelihood ration statistic:

$$
G^{2}\left(M \mid M^{\prime}\right)=D(M)-D\left(M^{\prime}\right) \xrightarrow{D} \chi_{p^{\prime}-p}^{2}
$$

Comparing logistic models
If the models are non nested, one can use:

$$
\begin{aligned}
& A I C(M)=D(M)+2|M| \\
& B I C(M)=D(M)+\log (n)|M|
\end{aligned}
$$

Data on ~100 subjects, ~250 SNPs

## Typical GWAS study approach

- Data QC
- Remove SNPs with $>5 \%$ missing data and or nonrandom missingness
- Remove SNPs with low Minor Allele Frequency
- Remove SNPs that depart from HWE
- Remove individuals with high percent of missing data
- Run logistic regression model for each of the SNPs
- Identify top SNPs with significant drug and SNP interaction
- Try to model interactions between top SNPs (later)
- Identify SNPs for candidate gene study

## Log linear models

- Alternative approach to model association between categorical variables
- Instead of modeling the response probability, expected cell counts are modeled: $\log \left(m_{\mathrm{ij}}\right)=\ldots$.

|  |  | $\mathrm{X}_{2}$ |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  | 1 | 2 |  |
| $\mathrm{X}_{1}$ | 1 | $\mathrm{n}_{11}$ | $\mathrm{n}_{12}$ | $\mathrm{n}_{1 .}$ |
|  | 2 | $\mathrm{n}_{21}$ | $\mathrm{n}_{12}$ | $\mathrm{n}_{2 .}$ |
|  |  |  |  |  |
|  |  | $\mathrm{n}_{\cdot 1}$ | $\mathrm{n}_{2}$ | n |

## Independence model

$\hat{m}_{i j}=\frac{n_{i \cdot .} n_{\cdot j}}{n}$
$\Rightarrow \log \hat{m}_{i j}=-\log n+\log n_{i .}+\log _{n . j}$
$\Rightarrow$ Model :
$\log m_{i j}=u+u_{1(i)}+u_{2(j)} \quad i=1,2 j=1,2$
$u_{1(1)}+u_{1(2)}=0, \quad u_{2(1)}+u_{2(2)}=0$

## General model for 2x2 table

Saturated model:

$$
\begin{aligned}
& \log m_{i j}=u+u_{1(i)}+u_{2(j)}+u_{12(i j)} \quad i=1,2 \quad j=1,2 \\
& u_{1(1)}+u_{1(2)}=0, \quad u_{2(1)}+u_{2(2)}=0 \\
& u_{12(1 j)}+u_{12(2 j)}=0 \text { for } j=1,2 \\
& u_{12(i 1)}+u_{12(i 2)}=0 \text { for } i=1,2
\end{aligned}
$$

Interpretation of parameters:
$u=\frac{1}{4} \sum_{i j} \log m_{i j} \quad$ The hypothesis of independence
$u_{1(1)}=\frac{1}{4} \log \frac{m_{11} m_{12}}{m_{21} m_{22}} \quad$ H0: $\begin{aligned} & 12(11)=0\end{aligned}$
$u_{12(11)}=\frac{1}{4} \log \frac{m_{11} m_{22}}{m_{21} m_{12}}$
etc.

Simple example

|  |  | SNP |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  | BB (1) | Bb or bb (2) |  |
| Response | No (1) | 2037 | 958 | 2995 |
|  | Yes (2) | 1757 | 218 | 1975 |
|  |  | 3794 | 1176 | 4970 |

## Analysis

## "Usual" chi-square analysis

## Connection between log-linear

 models and logistic regression
## 4.

## v

- Assuming independence:

$$
\begin{aligned}
& \log \frac{P\left(X_{1}=2 \mid X_{2}=j\right)}{P\left(X_{1}=1 \mid X_{2}=j\right)}=\log \frac{P\left(X_{1}=2, X_{2}=j\right)}{P\left(X_{1}=1, X_{2}=j\right)}= \\
& =\log \frac{p_{2 j}}{p_{1 j}}=\log \frac{m_{2 j}}{m_{1 j}}=\log m_{2 j}-\log m_{1 j}= \\
& =\left(u+u_{1(2)}+u_{2(j)}\right)-\left(u+u_{1(1)}+u_{2(j)}\right)= \\
& =u_{1(2)}-u_{1(1)}
\end{aligned}
$$

- This is the intercept only logistic regression

$$
\log \frac{P\left(X_{1}=2 \mid X_{2}\right)}{P\left(X_{1}=2 \mid X_{2}\right)}=\beta_{0}
$$

## What about a saturated model?

- Similarly we receive

$$
\log \frac{P\left(X_{1}=2 \mid X_{2}=1\right)}{P\left(X_{1}=1 \mid X_{2}=1\right)}=\left(u_{1(2)}-u_{1(1)}\right)+\left(u_{12(21)}-u_{12(11)}\right)
$$

$$
\log \frac{P\left(X_{1}=2 \mid X_{2}=2\right)}{P\left(X_{1}=1 \mid X_{2}=2\right)}=\left(u_{1(2)}-u_{1(1)}\right)+\left(u_{12(22)}-u_{12(12)}\right)
$$

- Which is actually a logistic regression model, with intercept an a term that depends on $\mathrm{X}_{2}$

$$
\log \frac{P\left(X_{1}=2 \mid X_{2}\right)}{P\left(X_{1}=2 \mid X_{2}\right)}=\beta_{0}+\beta_{1} X_{2}
$$

One variable independent of two others [1][23]:
X 1 is independent of $\{\mathrm{X} 2, \mathrm{X} 3\}$

$$
\log m_{u j k}=u+u_{1(i)}+u_{2(j)}+u_{3(k)}+u_{23(j k)}
$$

No second order interaction [12][13][23]: no clear interpretation

$$
\begin{aligned}
\log m_{u j k}= & u+ \\
& +u_{1(i)}+u_{2(j)}+u_{3(k)}+ \\
& +u_{12(i j)}+u_{13(i k)}+u_{23(j k)}
\end{aligned}
$$

## Association molecule

## Bayesian approach

- The log-linear models fail when one (or more) of the cells in the contingency table has a frequency of zero
- A common fix for that is to replace the zero by 0.5 or by 1
- This approach is criticized since the data is perturbed
- A possible approach is the Bayesian approach
- The count data is multinomial, but what if we assume that the multinomial distribution parameters are also random variables?

## Model setup

- Let $D$ be the observed cell count for a $2 \times 2$ contingency table: $\mathrm{D}=\left\{\mathrm{n}_{11}, \mathrm{n}_{12}, \mathrm{n}_{21}, \mathrm{n}_{22}\right\}$
- The data $D$ could have arisen under two hypotheses
- $H_{1}: X_{1}$ and $X_{2}$ are independent
- $H_{2}: X_{1}$ and $X_{2}$ are not independent
- Before seeing the observed data, we assume a priori that both hypotheses are equally likely:

$$
P\left(H_{1}\right)=P\left(H_{2}\right)=0.5
$$

## Applying Bayes theorem

$P\left(H_{i} \mid D\right)=\frac{P\left(D \mid H_{i}\right) P\left(H_{i}\right)}{P(D)}$
$\Rightarrow \frac{P\left(H_{2} \mid D\right)}{P\left(H_{1} \mid D\right)}=\frac{P\left(D \mid H_{2}\right) P\left(H_{2}\right)}{P\left(D \mid H_{1}\right) P\left(H_{1}\right)}=B_{21} \cdot \frac{P\left(H_{2}\right)}{P\left(H_{1}\right)}$
where $B_{21}$ is the Bayes Factor
$B_{21}=\frac{P\left(D \mid H_{2}\right)}{P\left(D \mid H_{1}\right)}$

- The Bayes Factor represent the ratio of the posterior odds of $\mathrm{H}_{1}$ to its prior odds

## Integrated likelihood

- $P\left(D \mid H_{i}\right)$ is the integrated likelihood of $D$, obtained by averaging the likelihood over all possible values of the parameters under $\mathrm{H}_{\mathrm{i}}$.
- What are the parameters?

Modeling the prior distribution

|  |  | SNP |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  | BB (1) | Bb or bb (2) |  |
| Response | No (1) | $\alpha$ | $\alpha$ | $2 \alpha$ |
|  | Yes (2) | $\alpha$ | $\alpha$ | $2 \alpha$ |
|  |  | $2 \alpha$ | $2 \alpha$ | $4 \alpha$ |

- Before seeing the data, we have no knowledge about which combination of categories are more or less likely
- The natural way to model the distribution of the multinomial parameters is the Dirichlet distribution - an extension of the Beta distribution, as it is conjugate the Multinomial distribution
$X=\left(X_{1}, \cdots, X_{k}\right) \sim \operatorname{Dirichlet}\left(\alpha_{1}, \cdots, \alpha_{k}\right) \sim \operatorname{Dirichlet}(\alpha):$
$f_{X_{1}, \cdots X_{k}}\left(x_{1}, \cdots, x_{k} \mid \alpha_{1}, \cdots, \alpha_{k}\right)=\frac{\Gamma\left(\alpha_{1}+\cdots+\alpha_{k}\right)}{\Gamma\left(\alpha_{1}\right) \cdot \ldots \cdot \Gamma\left(\alpha_{k}\right)} \cdot x_{1}^{\alpha_{1}-1} \cdot \ldots \cdot x_{k}^{\alpha_{k}-1}$
if $\quad \beta \mid X \sim \operatorname{Multinomial}(X)$
and $\quad X \sim \operatorname{Dirichlet}(\alpha)$
then $X \mid \beta \sim \operatorname{Dirichlet}(\alpha+\beta)$

Assuming $\mathrm{H}_{2}$ - interaction

$$
\begin{aligned}
& P(D \mid p)=M \cdot p_{11}^{n_{11}} \cdot p_{12}^{n_{12}} \cdot p_{21}^{n_{21}} \cdot p_{22}^{n_{22}} \\
& P\left(p_{11}, p_{12}, p_{21}, p_{22} \mid \alpha\right)=\frac{\Gamma(4 \alpha)}{\Gamma(\alpha)^{4}} p_{11}^{\alpha-1} \cdot p_{12}^{\alpha-1} \cdot p_{21}^{\alpha-1} \cdot p_{22}^{\alpha-1} \\
& P\left(p_{11}, p_{12}, p_{21}, p_{22} \mid D, \alpha\right)= \\
& \frac{\Gamma(n+4 \alpha)}{\Gamma\left(n_{11}+\alpha\right) \cdot \Gamma\left(n_{12}+\alpha\right) \cdot \Gamma\left(n_{21}+\alpha\right) \cdot \Gamma\left(n_{22}+\alpha\right)} \cdot p_{11}^{n_{1}+\alpha-1} \cdot p_{12}^{n_{12}+\alpha-1} \cdot p_{21}^{n_{2}+\alpha-1} \cdot p_{22}^{n_{22}+\alpha-1}
\end{aligned}
$$

## Integrated likelihood under $\mathrm{H}_{2}$

$P\left(D \mid H_{2}\right)=$
$=\int p_{11}^{n_{11}} p_{12}^{n_{22}} p_{21}^{n_{21}} p_{22}^{n_{22}} P\left(p_{11}, p_{12}, p_{21}, p_{22} \mid \alpha\right) d p_{11} d p_{12} d p_{21} d p_{22}=$
$=\frac{\Gamma(n+4 \alpha)}{\Gamma\left(n_{11}+\alpha\right) \cdot \Gamma\left(n_{12}+\alpha\right) \cdot \Gamma\left(n_{21}+\alpha\right) \cdot \Gamma\left(n_{22}+\alpha\right)} \cdot \frac{\Gamma(\alpha)^{4}}{\Gamma(4 \alpha)}$

## Assuming $\mathrm{H}_{1}$ - independence

- $\mathrm{P}_{\mathrm{ij}}=\mathrm{p}_{\mathrm{i} .} \cdot \mathrm{p}_{\mathrm{j},}$, therefore:

$$
P(D \mid p)=M \cdot p_{1 .}^{n_{1}} \cdot p_{2 .}^{n_{2}} \cdot p_{.1}^{n_{1}} \cdot p_{.2}^{n_{2}}
$$

- Assume independent Dirichlet prior for raw and columns marginal probabilities:

$$
\begin{aligned}
& P\left(p_{1 .}, p_{2 .} \mid \alpha\right)=\frac{\Gamma(4 \alpha)}{\Gamma(2 \alpha)^{2}} p_{1 .}^{2 \alpha-1} \cdot p_{2 .}^{2 \alpha-1} \\
& P\left(p_{.1}, p_{.2} \alpha\right)=\frac{\Gamma(4 \alpha)}{\Gamma(2 \alpha)^{2}} p_{.1}^{2 \alpha-1} \cdot p_{.2}^{2 \alpha-1}
\end{aligned}
$$

## Integrated likelihood under $\mathrm{H}_{2}$

$P\left(p_{1 .}, p_{2,}, p_{.1}, p_{.2} \mid D, \alpha\right)=$
$\frac{\Gamma(n+4 \alpha)}{\Gamma\left(n_{1 .}+2 \alpha\right) \Gamma\left(n_{2 .}+2 \alpha\right) \Gamma\left(n_{1}+2 \alpha\right) \Gamma\left(n_{2}+2 \alpha\right)} \cdot p_{1 .}^{n_{1}+2 \alpha-1} p_{2 .}^{n_{2}+2 \alpha-1} p_{.1}^{n_{1}+2 \alpha-1} p_{.2}^{n_{22}+2 \alpha-1}$

$$
\begin{aligned}
& P\left(D \mid H_{1}\right)= \\
& \frac{\Gamma(n+4 \alpha)}{\Gamma\left(n_{1 .}+2 \alpha\right) \cdot \Gamma\left(n_{2 .}+2 \alpha\right) \cdot \Gamma\left(n_{.1}+2 \alpha\right) \cdot \Gamma\left(n_{.2}+2 \alpha\right)} \cdot \frac{\Gamma(2 \alpha)^{4}}{\Gamma(4 \alpha)^{2}}
\end{aligned}
$$
